

Milk Production and Release

(2) Once stimulated, the pituitary releases two hormones, prolactin and oxytosin into the blood stream. These quickly arrive at their target tissues to have the desired effect.

Hypothalamus
 Prolactin Releasing Hormone is increased and Prolactin Inhibiting Hormone
 Oxytosin is secreted by neurosecretory cells into the blood stream.

Gonadotropin Releasing Hormone (GnRH) is inhibited. Therefore FSH is not secreted and follicle development is depressed.

Note: The afferent pathway is a nervous system response and the efferent pathway is an endocrine system response. The primary control center is the hypothalamus of the brain. Muscular and glandular effectors are located in the breasts. Receptors are located in the region of the nipple.

(3) Prolactin stimulates milk production

(4) Oxytosin stimulates milk ejection

(1) Nipple Stimulation during breast feeding sends a nerve impulse to the brain (hypothalamus) which in turn will stimulates the pituitary gland to release oxytosin and prolactin.
